LIST OF PLANS

1 SUMMARY

EL8313 lies approximately 25km north of Pine Creek township and is easily accessed by a well formed gravel road. The road, built to service the Frances Creek Iron mines is serviceable all year except when it is "closed" following heavy rainfalls. Away from the main access road motorised access is extremely difficult due to the steep topography and deeply incised Creeks.

During the 1996 field season (March to November) a comprehensive first pass exploration program has been applied to most of the licensed area and some follow-up work completed. The activities concluded include various forms of geochemical sampling, geological line mapping, EM surveying and magnetic data interpretation. this activity culminated in the drilling of three holes to test various targets. Two RC holes were drilled to test purely geochemical targets and one RC/diamond hole was completed to test a geophysical target.

Those areas drilled have proved disappointing with assay results well below expectation. In the areas tested with drill holes, it is difficult to see that any further work which could lead to the discovery of significant mineralisation.

2 INTRODUCTION

2.1 Access and Physiography

EL8313 lies approximately 25km by road north of Pine Creek township (Figure 1). Pine Creek is situated 230km south of Darwin along the Stuart Highway. From Pine Creek travelling 3km along the Kakadu Highway then turning north onto the well made Frances Creek road and covering 25km leads directly to the project area. All roads in the area are subject to closure or become impassable due to heavy seasonal rains between November and March.

Within the project area vehicle access is heavily restricted by steep sided hills and deeply incised Creeks. Following the wet season long grass, 1m to 2m high restricts both vehicle and pedestrian traffic away from the main road. One poorly formed and unmaintained track leads from the Frances Creek road to an abandoned airstrip in the south-central portion of EL8313. This track when visible, after burn-off, provides limited access to the south-central and the eastern edge of the project area.

2.2 Tenure

EL8313 was granted to Norman Sydney McCleary on 31 December, 1993, for a period of 5 years. The original licence covered almost 9 graticule blocks (a small area of freehold land in the abandoned township of Frances Creek was excluded) bounded by latitudes 13° 37"S and 13° 40"S and longitudes 131° 50"E and 131° 53"E (Figure 2). The licence has been reduced to five graticule blocks effective from 31 December, 1995. No relinquishment is planned for the next year of the licence.

Background land tenure under EL8313 is Mary River West Pastoral Lease (PL815). An area of freehold land (Frances Creek township) straddles the boundary between the EL8313 and AN389 which abuts the licence on its northern boundary.

2.4 Previous Exploration and Mining

Within AN389 and EL8313 previous mining activity has been restricted to the iron deposits to the east and northeast of Frances Creek. According to Ahmad *et. al.* (1993) these were discovered in 1962 and mined by the Frances Creek Iron Mining Corporation Pty Ltd between 1966-1974. A total of 8 million tonnes grading 59% Fe were produced, the bulk (6.1 million tonnes) from the Helene No. 6 and 7 lodes within AN389. The iron ore occurred as a series of massive hematite lodes conformable within tight to open folded pyritic, carbonaceous shales near the base of the Wildman Siltstone. The ore consists of massive and micaceous hematite with included shale and quartz grains in varying proportions. Ahmad *et. al.* (1993) postulate that the ore developed by oxidation of a pyritic horizon though no drillholes have penetrated this unit in the primary zone to confirm this interpretation.

After the cessation of mining activity and surrender of the original titles the area was held within a Mining Reserve because of the extent of surface disturbance caused by the operations. Consequently, up until the grant of the current titles the area was not available for systematic exploration and hence escaped the detailed investigations for gold conducted throughout the surrounding region over the past decade.

Since the current titles were granted, reconnaissance soil sampling was completed in 1994 by the title holder over the rocks of the South Alligator Group (Hardy, 1995). These crop out in a band about 0.5-0.8 kilometres wide along the western margin of AN389 and in the northwest corner of EL8313. A total of 135 samples were collected at 25 metre intervals and composited to 100 metre samples along 15 lines spaced 400 metre apart. Samples were analysed for gold (BLEG) and arsenic. Two weak but distinct linear gold-arsenic anomalies, each 2 to 2.5 kilometres long and with values to 30 ppb Au and 120 ppm As, were defined. These coincided with westerly dipping Koolpin Formation metasediments which form the hanging-wall of a metadolerite sill at the base of the unit. Further detailed soil sampling, rock-chip sampling and mapping were recommended.

In November 1995, Homestake Gold of Australia Limited (HGAL) commissioned a soil sampling program over the western portion of the licences. The survey was situated to test the extent of the Koolpin Formation. The grids referred to as the northern and southern were pegged at 50m on lines 100m apart.

Approximately 550, -20# samples were collected on 100m spaced lines. The samples were composited from material collected 15m east, 15m west and at the 50m spaced peg. In all cases the top 10cm of material was described prior to sieving the sample. The majority of samples were sieved in the field however due to wet conditions some bulks were collected, dried at Assaycorp, Pine Creek and then disaggregated and sieved. All samples and duplicates were assayed for gold by Assaycorp.

3 GEOLOGICAL SETTING

AN389 and EL8313 straddle the contact between metasediments and metadolerites of the Early Proterozoic Pine Creek Geosyncline succession and the later, though still Early Proterozoic, intrusive Allamber Springs Granite, part of the Cullen Batholith (Figure 3) The regional stratigraphy and geological relationships are summarised in Table 1 and are described in more detail in recent accounts by Ahmad *et. al.* (1993) and Stuart-Smith *et. al.*(1993).

The metasediments within the titles under review largely belong to Wildman Siltstone and Mundogie Sandstone of the Mount Partridge Group. These unconformably overlie the Masson Formation of the Namoona Group in the south east of corner of AN389 and are unconformably (?, weak warping) overlain by the Koolpin Formation and Gerowie Tuff of the South Alligator Group along the western margin of AN389 and the northwestern corner of EL8313. Metadolerite sill of the syn-sedimentary Zamu Dolerite intrude the Koolpin Formation and the contact between the Koolpin Formation and underlying Wildman Siltstone.

According to the published 1:100,000 geological map of the area (Pine Creek) the Masson Formation consists mainly of carbonaceous phyllite, slate, silty phyllite and sandy siltstone with minor quartzite and massive ironstone and rare tremolite marble. The Mundogie Sandstone is comprised of coarse pebbly feldspathic quartzite, arkose and micaceous quartzite with minor chert and pebble conglomerate. The Wildman Siltstone is divisible into to units. The upper part consists dominantly of siltstone, phyllite, carbonaceous phyllite and minor laminated coarse sandstone whereas the lower part includes mainly pyritic carbonaceous phyllite, siltstone and pyritic carbonaceous shale breccia (massive hematite ironstone lenses on the surface). In the South Alligator Group, the Koolpin Formation consists mainly of ferruginous (pyritic and pyrrhotitic) and carbonaceous phyllite with horizons of laminated, lensoidal and nodular chert along with minor dolomite and marl. The Gerowie Tuff is comprised of grey siltstone interlayered with crystal tuff, lithic tuff and black cherty tuff as well as minor laminated chert.

The Zamu Dolerite sills are composed of chloritised quartz dolerite and amphibolite.

Adjacent to the contact with the sediments and dolerites, the Allamber Springs Granite is composed mostly of pink, coarse, equigranular and porphyritic, biotite granite while further from the contact, in the southern half of EL8313, pink-green coarse porphyritic hornblende-biotite granite and pink-grey fine to medium equigranular leucogranite and alkali feldspar granite sequentially dominate. Greisen stockwork is extensively developed within a kilometre or two of the contact

The metasediments and metadolerite sills are folded about upright folds which plunge at a shallow angle to the north-northwest. Folding was accompanied by lower greenschist regional metamorphism. The folding and the regional metamorphism are overprinted by the effects of granite intrusion. The granite contact truncates the folded sequence in a passive fashion and albite-epidote hornfels and hornblende hornfels facies contact metamorphism overprints the regional metamorphic assemblages progressively closer to the contact. A distinctive feature of the contact metamorphism is the development of fine white andalusite (chiastolite) needles in the more aluminous black carbonaceous meta-mudstones of the Masson Formation, Wildman Siltstone and Koolpin Formation.

Flat-lying Mesozoic sandstone, siltstone and conglomerate unconformably overlie all of the Early Proterozoic rocks in the area. Several remnant outliers of these rocks are present in the Frances Creek area and one of these is within the eastern part of AN389 (Figure 3). They form flat topped mesa-like landforms above an elevation of 240 metres ASL. According to Ahmad *et. al.* (1993) these sediments were originally mapped by Skwarko (1966) as Mullaman Beds but were interpreted by Hughes (1978) as belonging to the Petrel Formation of Jurassic to Lower Cretaceous age and the Darwin Member of the Bathurst Island Formation of Lower to Upper Cretaceous age.

Finally Cainozoic alluvial and colluvial sand, silt clay and gravel are deposited across the area and as pointed out by Ahmad *et. al.* (1993) these are separated from the basement rocks by residual laterite in many areas.

Four main styles of gold mineralisation are known to occur throughout the region. These occur exclusively within the metasediments and metadolerites of the Pine Creek Geosyncline sequence and almost without exception above the stratigraphic level of the middle of the Koolpin Formation in the South Alligator Group.

Of prime interest is gold mineralisation of the Cosmo-Howley/Golden Dyke style which is hosted by silicate-sulphide facies, cherty iron formations in the middle and upper levels of the Koolpin Formation. At the Golden Dyke Mine (and adjacent smaller deposits), 35 kilometres west of Frances Creek, the mineralisation occurs as a stratiform lens on the western side of the Golden Dyke Dome. At the Cosmo Howley Mine, 50 kilometres west of Frances Creek, similar stratiform mineralisation occurs on the limbs and the crest of the Cosmo Anticline where it has been complicated by, and possibly remobilised and upgraded by, strong axial plane faulting and nearby granite intrusion.. To date no mineralisation of this type has been discovered below the iron formations in the Middle Koolpin Formation. Similar mineralisation occurs at Mount Porter, 2.5 kilometres west of the Frances Creek titles.

Around the Golden Dyke Mine there is also extensive development of bedded tourmalinite (5-30 metres thick, several kilometres in strike extent) at the same stratigraphic level as the gold mineralisation but laterally removed from it. In that area lenses of stratiform gold mineralisation (and tourmalinites) occur in at least two and possibly more stratigraphic levels in and above the middle of the Koolpin Formation.

Of secondary interest in this area is sulphide-associated gold mineralisation in the Zamu Dolerite sills which occur at several levels in the Koolpin Formation and overlying Gerowie Tuff. Mineralisation of this style was mined from the Chinese Howley South deposit a few kilometres north of the Cosmo Howley Mine and it also occurs at Margaret Diggings 7 kilometres southeast of the Golden Dyke Mine and at the Quest 29 prospect in the Mount Bundey area. In these deposits the gold occurs mainly in discontinuous quartz-sulphide veins and reefs which in places are concentrated sufficiently close enough to form coherent mineable resources. Some disseminated mineralisation is also present. This style of gold mineralisation is considered by some to constitute a remobilisation of stratiform gold mineralisation from enveloping units of the Koolpin Formation but others have explored for this style of gold mineralisation in dolerites in this region using dolerite-hosted gold mineralisation at Kalgoorlie as the empirical model.

Of lesser importance in the Frances Creek titles, but of major importance elsewhere in the region, is gold mineralisation in sheeted and stockwork and saddle quartz-pyrite vein systems. This type of mineralisation is generally developed along the crest and limbs of major regional anticlines and is almost exclusively hosted by tuffaceous greywacke-siltstone sequences above the Koolpin Formation. Significant examples of stockwork-type gold mineralisation (as this type is collectively described) in the region include the Enterprise Mine at Pine Creek (1.3 million ounces of production and resources) the Batman deposit at Mount Todd further to the south (2-3 million ounces of reserves and resources) and the Union Reef, Brocks Creek, Rustlers Roost, Goodall and Woolwonga deposits. Lesser deposits include Chinese Howley, Big Howley, Spring Hill, Yam Creek, Fountain Head and Western Arm. Stratiform gold mineralisation hosted by pyritic chert and banded iron formation in the Gerowie Tuff is known at the Zapopan mine and this may also be part of this group.

Stratiform poly-metallic base metal mineralisation (with associated gold) occurs at Mount Bonnie and Iron Blow, 30 kilometres west of Frances Creek. In both cases it is hosted by the lower Mount Bonnie Formation. While there have been several intense exploration programmes in the region seeking this type of mineralisation in the carbonaceous sediments of the underlying Koolpin Formation, they have met with only very limited success.

Because of the stratigraphic position of the Frances Creek titles they are highly prospective for mineralisation of the Cosmo Howley/Golden Dyke-type, especially in the Middle and Upper Koolpin Formation.

4 EXPLORATION ACTIVITIES 1996

4.1 -20# Soil Sampling - South Grid

The results of the 1995 sampling program were encouraging with several areas of anomalous gold and arsenic delineated.

Results of the initial soil sampling in 1995 defined two areas of interest in the south grid. The first of these is centred about 91800N, 7300E and covers an area 300m long and 200m wide . The best result was 457ppb Au with several results above 25ppb. The anomaly was open to the north-east. The second area of interest occurred on the southern most line of survey and consisted of three samples in a row with the centre being 29.6ppb Au flanked by results greater than 10ppb Au. This anomaly was open to the south.

Field inspection of the southern grid anomalies indicated the gold response were being generated by highly sericitic greisenised granite with iron straining after pyrite. During the inspection a rock chip sample of the greisen was taken which returned 0.43ppm Au.

To better define and close the anomalous responses a program of infill and extension sampling was conducted. The sampling was done in several passes during May and June 1996. The sampling method employed was identical to the first survey and the program concluded anomalous areas had be sampled at a 50 x 50m spacing. In the second program samples were collected and assayed for gold and arsenic.

Figures 4 and 5 show the sample locations and analytical results. Appendix 1 lists the assay results.

The results of the "infill" program were enigmatic in that while anomalous responses were generated where expected the level of anomalism was lower than previously described. The difference was so distinct that enquires were made with Assaycorp to seek possible explanations. Following Assaycorp's suggestion that the variation may in some way be attributable to difference in weight of samples collected in the two programs a short re-sampling program was conducted.

In this program four samples of different weight were taken from 10 sites sampled in 1995. The samples were sieved in field and the samples submitted to the laboratory in randomised order. As an additional check on field technique one sample was sieved at -40# while the rest were at -20#. Table 1 displays the sample number, mesh size, location and gold results for the different weights of sample and volume of digestion. The results of this work were also inconclusive but it is believed that either some problem of a non-reproducible nature may have occurred at the laboratory or that levels of extractable gold in the soils vary with the seasons. Nevertheless, while the values obtained in the 1996 sampling are subdued the anomalous pattern is present and the data can be used.

4.2 Stream Sediment Sampling

A regional stream sediment sampling program was completed over most of the Frances Creek project area in April and May. This survey involved the collection of 2kg, -2.5mm samples and 150g, -40# samples at 78 sites within AN389 and EL8313. In addition 11, -6mm samples weighing 5kg or more were collected. Each site was permanently marked by permatag and a GPS position recorded. The -2.5mm, 2kg samples were assayed for gold via the BLEG technique while the -40# samples were analysed for arsenic using a hydride generation technique at Assaycorp. The 11 -6mm bulk samples were analysed by Analabs using a variation on the BLEG technique.

Figure 6 shows the sample site locations and the gold and arsenic responses. Analytical results are listed in Appendix 2.

The results of the stream sediment sampling program were as expected with one areas of anomalous drainage defined in EL8313. This originates from the area of gold-in-soil anomalism delineated in the South Grid.

4.3 Line Mapping

A limited amount of line mapping has been completed with the Frances Creek project area. The mapping was conducted to facilitate and augment the interpretation of geochemical responses. In the South Grid mapping was carried out to accurately plot the granite-sediment contact in the southern part of EL8313 and limited detailed line mapping was undertaken to delineate the zone of sericite alteration and the granite-dolerite contact.

In the East Grid 1:5000 scale line mapping of the Mt Partridge Group between 92400N and 92800 north was completed. Plan 1 shows the fact geology. The mapping was undertaken to try and provide a basis upon which the EM survey results could be interpreted. However, attempts to produce a meaningful geological interpretation were abandon when it became apparent that insufficient, consistent geological information could be collected at this scale. The principal problems were poor rubbly outcrop with abundant scree slopes; coarse-grained units which failed to preserve subtle fabrics uniformly; and numerous late stage small scale folds which effectively mask larger structures and stratigraphic trends.

4.4 EM Survey

To further investigate the economic potential of the Mt Partridge Group area, an EM survey was conducted over that part of the East Grid area within EL8313. The survey consisted of two 800 x 400m fixed loops located to evaluate the possible conductance associated with magnetic anomalies delineated in 1995. To facilitate the survey a detailed grid was established with lines 200 metres apart pegged at 50m spacing over the area shown in Figure 2. The gridding was completed by Arnhem Geological and Exploration Service Pty Ltd.

The EM data was collected by Outer-Rim Exploration Services. Interpretation of the results was undertaken by G.O. Dickson and associates. Their report is included as Appendix 3.

4.5 Aeromagnetic Data Interpretation

The aeromagnetic data collected and processed in 1995 was examined and modelled by G.O. Dickson and Associates. Their findings are discussed in their report included as Appendix 3.

4.6 Drilling

Two reverse circulation (RC) holes and one reverse circulation/diamond drill hole were completed in EL8313 in 1996. The holes were designed to test targets where stream and soil geochemical sampling, conceptual models and geophysical interpretations suggested the possibility of locating significant mineralisation. In all cases the RC component of the holes was sampled as 2m composites and submitted to Assaycorp, Pine Creek. The diamond core was geologically logged, susceptibility measurements were taken throughout and selected intervals of cut core were analysed.

The location of the drill holes are shown on Figure 7. Geological logs and assay results for the RC holes (FCRC001-002) are contained in Appendix 4 and plotted on Plans 2 and 3. Appendix 5 contains the geological and geophysical logs and assay results for the diamond drill hole (FCDH008). The geology and assays for FCDH008 are also plotted on Plans 4 and 5. Table 3 contains a summary of the drilling details

FCRC001 and 002 were drilled to test alteration zones within the basement granite. The assay results in conjunction with the geological logs clearly demonstrate the positive association of gold mineralisation with alteration. In FCRC001 the zone 22-32m is green sericitic granite with pyrite and rare arsenopyrite. The assay results, although subdued, show a corresponding elevation with 0.19 g/t Au and 2800ppm As the maximum values for a 2m interval. Similarly in FCRC002 the interval 12-25m is sericite-pyrite granite and has elevated gold responses with 0.56g/t Au as the maximum.

The combined RC/diamond drill hole was completed at 192m in almost pure, well bedded dolomite-marble (Appendix 5). At the (magnetic) target depth of 80m the lithology changes from a grey pyritic siltstone/mudstone to a dark grey-black graphitic, highly pyrrhotitic mudstone. This persists to 128.9m and is cut by occasional granitic dykes and/or sills. Susceptibility measurements in this zone are sufficiently strong to explain the aeromagnetic anomaly.

TABLE 3: DRILL HOLE DETAILS, EL8313, FRANCES CREEK SOUTH

Hole No	Easting	Northing	RL	Azimuth (Mag)	Incln	Depth (m)

HOMESTAKE AUSTRALIA

FRANCIS CREEK REPORT

TEM and AEROMAGNETIC DATA

PREPARED BY:-
G O DICKSON & ASSOCIATES

AUGUST 1996

1.0 INTRODUCTION

Aeromagnetic data were collected over the Francis Creek and Mount Porter areas which are located near Pine Creek in the Northern Territory.

The Francis Creek aeromagnetic data were used to locate six, time domain electromagnetic (TEM) transmitter (TX) loops to investigate the major magnetic anomalies. The TX loops measured 800 by 400 metres. The geology of the area was not well known and the surveys were designed to test for both steep and flat lying conductors.

Outer-Rim Exploration Services were invited to carry out the surveys using a Crone TEM system.

An interpretation of the TEM and aeromagnetic data is presented in this report.

2.0 ITEMS ACCOMPANYING THIS REPORT

All plans and images are at scale of 1:10,000 scale

1 TEM images of the vertical field component for loops 1,2 and 4 and for loops 3,6 and 7.

2 TEM images for the Y component for each of the six loops surveyed.

3 Images of the pole reduced magnetic data and the 1st vertical derivative (1V

4 Interpretation plan drafted on the 1VD image

3.0 CONCLUSIONS & RECOMMENDATIONS

1 The results of the TEM surveys were disappointing and the data are difficult to interpret. The response appears to be due to an earth whose conductivity increases with depth or to a layered earth where the deeper layers become more conductive. The response tends to be 'lock in' under the TX loops with a slow drift and shrinkage with time. Only two conductors, other than those associated with the loops, are mentioned. The source of C1 is likely current channelling and no follow up appears warranted. The position of C2 coincides with one of the shallowest magnetic bodies but it is unlikely that the magnetic body is the source of the TEM anomaly. The TEM anomalies also occur in areas where the depth to the magnetic source is much deeper.

2 We favour drill testing magnetic anomalies A and C. A could be relatively shallow and as bodies A and B are likely fault related it will provide a clue to the source of anomaly B with is much deeper. Magnetic body C is relatively shallow with perhaps a very gentle plunge to the north. A test on anomaly C would also provide an answer to source of the TEM anomalism.

4.0 INTERPRETATION- TEM DATA

Profiles for the Z component (+ve down at loop centre) and a horizontal component (X +ve in line & Y +ve north) are included under separate cover. Both in-loop and out-of-loop surveys were carried out as the geological attitude was not known.

The TEM response is not easy to understand. It is one of the most difficult TEM problems that I have encountered.

Reports submitted to Homestake by Outer-Rim show that the Z component response out to channel 30, ~13 ms (channel 30 is one of 35 maximum channels) stays fixed near the TX loop. We have combined the results for loops 1,2,4(out-of-loop surveys) into image 1 and those for loops 3,6,7(in-loop-surveys) into image 2. In the join of grids, the out-of-loop response should be 'continuous' for steeply dipping bodies. This is clearly not the case. The conclusion is that the response is dominated by the ground and the Z-component will be stronger under the TX loop. See the in-loop data, image 2.

In the case of the ground response, the rate of decay of the TEM response is diagnostic. The half space and the conductive layer will decay at different, but at predicable rates. Horizontal components always decay faster than the vertical components. *Predicable rates of decay are not achieved* except at very late time. Short of seeking an instrument problem (and we have no grounds for that) we suggest:-

- The conductivity of the earth continues to increase with depth in a smooth way from a more resistive surface reaching quite conductive material at depth. The induced ground response is confined to the conductive material for times beyond the resolution of most TEM equipment. We also imagine that the lower layers are folded or faulted and give rise to conductivity contrasts where current channelling may occur.

- The only way that we can explain the decay of horizontal components being slower than the vertical component is to assume a variable thickness or conductivity of the underlying material. Certainly, the centre of the maximum vertical field response may move with time with respect to the centre of the TX loop and this can result in unusual rates of decay for all components. In some cases, the late time rate of decay tends towards an exponential and this is unexpected for an unconfined conductor.

- Variability of conductivity and thickness of near surface material is not taken into account in the theoretical work and this variability can account for the departure from expected rates of decay.

4.1 LOOP SUMMARY

The vertical field response for loops 1,2 and 4 (out-of-loop surveys) are combined in image 1. The in-loop vertical field response in combined in image 2. To achieve better resolution, the results for loop 2 are reproduced in image 3. The Y component response cannot be combined (because of polarity changes across the loop) and presented in individual images. We note that in some cases the horizontal field response is distorted near the loop and this, no doubt, is due to a small misalignment of the coil.

LOOPS 1 AND 7. The response to the surveys from these two loops can be explained as set out in the general discussion above. There are no other TEM anomalies that warrant mention.

LOOPS 2 AND 3. An anomalous response is noted on several lines of this survey. The anomaly is best seen on image 3 (vertical field) and the corresponding Y field response where a very distinctive low, which corresponds to the axis of the conductor, strikes NW. The conductor is labelled C1 and its position is shown on the magnetic interpretative plan. The attitude of the conductor is such that it cannot be detected by the in-loop survey of loop 3. The conductor is in a position of poor coupling for the loop 3 survey. We suggest that the source of the anomaly is current channelling.

LOOPS 4 AND 6. The loop 4 results suggest some change in conductivity near the edge of one of the shallowest magnetic anomalies in the area. The results are confirmed by the loop 6 data where the peak Z field response lies directly over the axis of the magnetic body. The horizontal field data also support an increase in conductivity over the magnetic axis (we note that the Y field data of loop 6 is noisy near the TX loop at late delay times). The conductor position is shown on the magnetic interpretative image.

4.2 SELECTED DECAYS

Numerous decay curves have been examined for these data. A selection of decay curves are included in the following figures to high light the unusual TEM responses encountered. Figure 1 shows the response for a station on loop 4 along with the theoretical response for a half space. Figure 1a is the response for the same station in log-linear form. The response is due to neither a half space nor a confined conductor. Figure 2 shows a very long time constant. The response in linear on a log-linear plot after about 15 ms and therefore suggests a confined conductor of good conductance. However, the Y component does not have the same decay. Figures 3 and 4 show examples of the horizontal component decaying more slowly than the vertical component; physically impossible for a layered earth or a half space. This behaviour is due to movement of the circulating currents. In figure 3 the Y field response rises as the current approaches the station. Figures 5 and 6 are other examples of slow horizontal field decay.

5.0 INTERPRETATION- MAGNETIC DATA

An image of the pole reduced magnetic data and the 1st vertical derivative (1VD) accompany this report. The 1VD image is also used as an interpretative plan.

Five profiles were cut from the data and the sections are numbered and shown in blue on the interpretative plan. The profiles were modelled to get some idea of the depth to the magnetic sources and the results are shown in the figures which follow. Briefly, the results suggest the following approximate depths in metres:-

MAGNETIC BODY	A	B	C	D
DEPH	80.	400.	120.	200.

Our interpretation of the magnetic data suggests two faults F1 and F2. F1 strikes roughly north east and separates A and B with right lateral movement and downward displacement to the north. F2 strikes roughly north south between B and C. The suggestion is upward movement to the east. An earlier interpretation of the Mt. Porter and Francis Creek magnetic data also suggested north south and north east faulting. Anomalies C and D may also be separated by a fault. Modelling suggests moderately high susceptibilities.

We are inclined to interpret the source of the magnetic bodies as doubly plunging folds with a shallower north plunge. We understand that a granite occurs to south of the magnetic bodies but it northern limit is not well defined by the magnetic data.

The position of conductors C1 and C2 are shown on the interpretative plan. C1 we belief is due to current gathering in the near surface material and is not directly related to magnetic source B. The position of conductor C2 is however intriguing. We doubt that the TEM source is directly related to the magnetic source but given the relatively shallow depth to the magnetic body it is a favourable position for a drill test.

		The rock consists of fine pink feldspar and pale grey, translucent quartz with minor amounts of hornblende partially altered to biotite. Thin grey veinlets of muscovite and pyrite occurs. Pyrrhotite occurs as isolated patches to 3mms. In restricted patches a pale green-yellow sericite occurs. Fractures are typically lined with dark chlorite and pyrite. Both the upper and lower contacts are conformable with bedding, sill. At 77.7mbc a small block of host sediment is incorporated (Xeno.lith). This contains coarse cordierite and poorly formed chiastolite/andalusite																							
76.15	83.45	Mudstone. A dark grey weakly graphitic mudstone with abundant white spots and streaks of well formed andalusite. Andalusite crystals occur to 1.5cm long. Pyrrhotite is by far the dominant		15	1:10		10		5	Tr			Tr						20			77.5	So	45

FCDH008

Grey to black graphitic mudstone with abundant coarse chiastolites.

Weathered grey siltstone.

Black graphitic mudstone.
Grey siltstone.
White coarse sandstone.

Partially weathered grey siltstone.

50 RC Pre-collar

Grey mudstone with light grey siltstone beds common. Abundant cordierite spotting and some small poorly formed chiastolites. Pyrite occurs throughout and pyrrhotite in discrete zones.

Pink partially altered granite.

Black weakly graphitic mudstone with abundant Andalusite and pyrrhotite in discrete beds.

Pink Granite.

Black graphitic mudstone with abundant andalusite and pyrrhotite in discrete beds to 30cm thick.

100 Granite with some pale green sericite.

A black mildly graphitic mudstone with occasional grey siltstone beds. Cordierite and andalusite are common. Pyrrhotite occurs in discrete beds and pyrite as thin veins and patches.

150

A white-grey Marble with abundant skyolites and minor small patches of pyrite.
